Wind Resource Mapping in Papua New Guinea

MESOSCALE MODELING REPORT

AUGUST 2015
This report was prepared by DTU Vindenergi and 3E, under contract to The World Bank.

It is one of several outputs from the wind resource mapping component of the activity “Renewable Energy Resource Mapping and Geospatial Planning – Papua New Guinea” [Project ID: P145864]. This activity is funded and supported by the Energy Sector Management Assistance Program (ESMAP), a multi-donor trust fund administered by The World Bank, under a global initiative on Renewable Energy Resource Mapping. Further details on the initiative can be obtained from the ESMAP website.

This document is an interim output from the above-mentioned project. Users are strongly advised to exercise caution when utilizing the information and data contained, as this has not been subject to full peer review. The final, validated, peer reviewed output from this project will be the Papua New Guinea Wind Atlas, which will be published once the project is completed.

1 INTRODUCTION & DISCLAIMER

The “Renewable Energy Resource Mapping – Wind Papua New Guinea, East Asia Pacific Region” activity is one of several country projects funded and supported by the Energy Sector Management Assistance Program (ESMAP) under a global initiative on Renewable Energy Resource Mapping. This document is an interim output from the above-mentioned World Bank project and outlines the preliminary mesoscale modelling results obtained in Phase 1 (Preliminary modelling and implementation planning) of the project.

The report by the Department of Wind Energy of the Danish Technological University (DTU) is contained as an annex to this report.

This document is based on an agreement entered into between the International Bank for Reconstruction and Development (“Client”) and 3E, and is intended for the sole use of Client, and no third-party beneficiaries are created hereby. To the extent permitted by law, 3E will not be liable (whether in contract, tort including without limitation negligence, or otherwise) to third parties.

This document has been prepared in good faith on the basis of information available at the date of publication without any independent verification. 3E does not guarantee or warrant the accuracy, reliability, completeness or currency of the information in this document nor its usefulness in achieving any purpose. Readers are responsible for assessing the relevance and accuracy of the content of this document. 3E will not be liable for any loss, damage, cost or expense incurred or arising by reason of any person using or relying on information in this document.

This document is protected by copyright and may only be reproduced and circulated in accordance with the associated conditions stipulated in 3E’s written agreement with Client. No part of this document may be disclosed in any public offering memorandum, prospectus or stock exchange listing, circular or announcement without the express and prior written consent of 3E. The fact that Client is permitted to redistribute this document shall not thereby imply that 3E has any liability to any recipient other than Client.

2 OBJECTIVES

The objective of this report is to describe the modelling strategy and method, show the output of the preliminary model results, and describe how these compare with a selection of existing measurement datasets.
3 METHODOLOGY

The methodology employed is the use of the Weather Research and Forecasting (WRF) model, driven by Climate Forecast System Reanalysis (CFSR) data at a resolution in the inner domain of 5 km. This inner domain covers the entirety of Papua New Guinea. The WRF model was run in a series of overlapping 11 day long simulations, run in parallel. The first 24 hours of each has been discarded to allow for model spin-up. Grid nudging was conducted on the outer domain above the boundary layer.

Output from the model was post-processed by the generalisation procedure developed at DTU. This procedure removes effects of surface roughness and topography as seen by the model so that these effects can be re-implemented by a higher resolution model (WAsP) at micro-scale model phase. The resulting output is a series of .lib files (WAsP – DTU) that describe the climatology at each point which can be used in further micro-scale modelling to define winds over a prospective wind farm site. More than 43000 generalised wind climate files have been created. This data has been presented in the form of a series of images showing mean and generalised maps of wind speed and wind power density.

The measurement data to be collected in Phase 2 will be crucial in configuring the model for optimal performance and for obtaining a sound understanding of the uncertainty associated with model results across the country.

Each of these points is detailed in the DTU meso-scale report attached in Annex A.

July 27, 2015
Abstract

This document reports on the methods used in Phase 1 of The World Bank wind mapping project for Papua New Guinea. The interim mesoscale modelling results were calculated from the output of simulations using the Weather, Research and Forecasting (WRF) model. We document the method used to run the mesoscale simulations and to generalize the WRF model wind climatologies. We also describe the special model settings, which were used to better represent the weather and climate characteristics of a equatorial island.

1 Introduction

The conventional method used to produce estimates of wind resource over large areas or regions, such as on a national scale, is to analyze wind measurements made at a number of sites around the region, as in for example the European Wind Atlas (Troen and Petersen, 1989). In order for this method to work well, there needs to be a good spatial coverage of high-quality data. This criterion is sometimes difficult to satisfy and therefore other methods are required that typically give good indications of the geographical distribution of the wind resource, and as such will be very useful for decision making and planning of feasibility studies. Numerical wind atlas methodologies have been devised to solve the issue of insufficient wind measurements. The latest methodology developed at at DTU Wind Energy uses the Weather Research and Forecasting (WRF) model in a dynamical downscaling mode to produce mesoscale analysis. It is this method that is employed in this study and described in this report. The method has recently been documented in Hahmann et al. (2014b) and verified against tall masts in the North and Baltic Sea.

This report is structured as follows: Sections 2 and 3 describe the general method and the specific modelling setup of the WRF modelling systems used in the generation of the Papua New Guinea phase 1 output. In Section 4 the results are presented, including some examples of local wind climates. Section 5 sets out a number of points of discussion and recommendation for how the modelling will be advanced in the next phase of the project, as well as recommendations for the project in general. Finally, Section 6 presents some conclusions.

2 Method

Numerical wind atlas methodologies have been devised to solve the issue of insufficient wind measurements. Two methodologies have been developed and used at DTU Wind Energy. The first methodology is the KAMM/WAsP method developed at Risø National Laboratory. It has been used extensively for a number of national projects. The origins of the method are described in Frank and Landberg (1997) and further details of the downscaling method developed are found in Badger et al. (2014). The KAMM/WAsP methodology has since been upgraded to use a newer and more sophisticated mesoscale model, namely the Weather Research and Forecasting (WRF) model.

The wind atlas method used in this study was calculated by carrying out a large number of 10 days mesoscale model simulations using the WRF model to cover a multiyear period. The output from the WRF simulations is analysed in a number of ways. For example, investigation
of the dynamic variation of wind speeds as a function of time of day and month of year. Specific meteorological phenomena in the model output relevant to wind energy can be investigated, and an understanding of the important meteorological phenomena is sought. To use the simulation data for wind resource assessment, the data must be post processed. This post processing includes calculating statistics from a very large dataset and the generalization of the wind climatologies. Wind climate estimates derived from mesoscale modelling and measurements can be compared in a proper way by the use of the generalization of the wind climatologies. Without the generalization step no verification is possible, because the surface description within the model does not agree with reality, and therefore modelled winds will not agree with measured winds, except perhaps in extremely simple terrain or over water far from coasts.

The generalization method has been used extensively in a number of wind resource assessment studies, particularly within the KAMM/WAsP method. The WRF wind atlas method with generalization and validation was first carried out within the Wind Atlas for South Africa project (WASA, 2014) and described in Hahmann et al. (2014a). For more details on the generalization method see Appendix A.

3 Modelling

The WRF Model (Skamarock et al., 2008) is a mesoscale numerical weather prediction system designed to serve both operational forecasting and atmospheric research needs. The simulations used to generate the interim wind modelling results utilize the Advanced Research WRF (ARW-WRF) version 3.5.1 model released on 23 September 2013. The WRF modelling system is in the public domain and is freely available for community use. It is designed to be a flexible, state-of-the-art atmospheric simulation system that is portable and efficient on available parallel computing platforms. The WRF model is used worldwide for a variety of applications, from real-time weather forecasting, regional climate modelling, to simulating small-scale thunderstorms.

Although designed primarily for weather forecasting applications, ease of use and quality has brought the WRF model to be the model of choice for downscaling in wind energy applications. This model was used in wind-related studies concerning: wind shear in the North Sea (Peña and Hahmann, 2012) and over Denmark (Draxle et al., 2014), organized convection in the North Sea (Vincent et al., 2012), low-level jets in the central USA (Storm et al., 2009), wind climate over complex terrain (Horvath et al., 2012), gravity waves (Larsén et al., 2012), extreme winds (Larsén et al., 2013), among many others.

3.1 Model setup

The simulations for the interim wind modelling were calculated on a grid with horizontal spacing of 45 km × 45 km (outer domain, D1, with 96 × 96 grid points), 15 km × 15 km (first nested domain, D2, with 187 × 187 grid points) and 5 km × 5 km (second nest, D3, with 325 × 397 grid points). Maps of the model domains are displayed in Fig. 1. The surface roughness length for innermost domain, D3, is given in Fig. 2.

In the vertical the model was configured with 50 levels with model top at 20 hPa. This is a special model configuration adapted to the occurrence of more deep convective activity in

</table>
Most choices in the model setup are fairly standard and used by other modelling groups. The only special setting for wind energy applications is the use of a constant surface roughness length, thus disabling the annual cycle available in the WRF model. This choice is consistent with the generalization procedure discussed in section 2 and Appendix A. A few other parameterization settings are updated for equatorial conditions compared to other wind atlas simulations: more vertical levels and raised model top, more sophisticated microphysics and convective scheme and updated radiation parameterizations.

![Diagram showing WRF model simulation schematic](image)

**Figure 3** – WRF model simulation schematic showing how the simulation period is covered by a succession of overlapping 11 day simulations. The first day of the simulations, which overlaps with the last day of the previous simulation, is for model spin-up and is not used in subsequent analysis.

The final simulation covered the 10-year period January 2004–December 2013, and was run in a series of 11-day long overlapping simulations, with the output from the first day of each simulation being discarded, see Fig. 3. This method is based on the assumptions described in Hahmann et al. (2010) and Hahmann et al. (2014b). The simulation used grid nudging that continuously relaxes the model solution towards the gridded reanalysis but this was done only on the outer domain and above the boundary layer (level 10 from the surface) to allow for the mesoscale processes near the surface to develop freely. Because the simulations were re-initialized every 10 days, the runs are independent of each other and can be integrated in parallel reducing the total time needed to complete a multi-year climatology. The grid nudging and 10-days reinitialization keeps the model solution from drifting from the observed large-scale atmospheric patterns, while the relatively long simulations guarantee that the mesoscale flow is fully in equilibrium with the mesoscale characteristic of the terrain.

### 3.2 Data processing

Wind speeds and directions are derived from the WRF model output, which represents 10-minutes or hourly instantaneous values. For evaluating the model wind speed climatology, the zonal and meridional wind components on their original staggered Arakawa-C grid were interpolated to the coordinates of the mass grid. The interpolated wind components were then used to compute the wind speed. For a given height, e.g., 100 m, wind speeds are interpolated
between neighboring model levels using logarithmic interpolation in height. It was found that this interpolation procedure preserves more of the original features in the model wind profile compared to other schemes (e.g., linear or polynomial interpolation of the wind components). The various data processing steps are shown in Fig. 4.

![Figure 4](image)

**Figure 4** – Schematic representation of the data processing used to create the wind climate files that compose the WRF-based NWA.

For each model grid point inside Papua New Guinea in domain D3 time-series for the entire period for the wind speed, wind direction at 5 heights, and $1/L$ were generated. The generation of the time-series is a rather time consuming process because the WRF output files are stored for every three hours for the whole domain. The generation of time-series requires that for every grid-point in the considered region all files for the whole period have to be accessed.

## 4 Results

In this section the results in the form of the annual mean wind climate are presented based on the 10 years of simulation, covering the years 2004 to 2013 inclusive. First the simulated winds are presented. These represent the annual mean wind speed and power density at 100 m a.g.l. directly from the modelling, see Figs. 5 and 6. Therefore, the winds in these maps reflect the orography and surface roughness length as they are represented in the model rather than the real orography and roughness length. Please note for the power density calculation only the air density is constant at 1.25 kg/m$^3$, so that variation of power density is due to variation of the wind speed distribution alone. Before wind power production is calculated it is important to account for air density at the site of interest.

Next the generalized winds are presented. These represent the annual mean wind speed and power density at 100 m a.g.l. for standardized condition of flat terrain with surface roughness length of 10 cm everywhere, as shown in Figs. 7 and 8. Now the winds in these maps reflect the variation of the winds due to all influences other than the microscale orography and surface roughness change. The figures show only a small part of the information contained in the generalized wind climate. An example of generalized wind climate file data is given in Fig. 9. Figure 10 shows the location of the 43587 generalized wind climate files that are created for every WRF model grid point inside Papua New Guinea and surrounding waters. These files can be used in the WASP software to calculate the predicted wind climate accounting for highly detailed microscale orography and surface roughness change effects for a particular site of interest.
Figure 5 – Mean annual simulated wind speed at 100 m a.g.l. from WRF simulation at 5 km × 5 km grid spacing for the period 2004 to 2013 inclusive. The colour scale indicates the wind speed in m s$^{-1}$.

Figure 6 – Mean annual simulated wind power density at 100 m a.g.l. from WRF simulation at 5 km × 5 km grid spacing for the period 2004 to 2013 inclusive. The colour scale indicates the wind power density in W m$^{-2}$. Note: for the power density calculation only the air density is constant at 1.25 kg/m$^3$. 
Figure 7 – Mean annual generalized wind speed at 100 m a.g.l. from WRF simulation at 5 km × 5 km grid spacing for the period 2004 to 2013 inclusive. The standard conditions are flat terrain with uniform surface roughness length (10 cm). The colour scale indicates the wind speed in m s$^{-1}$.

Figure 8 – Mean annual generalized wind power density at 100 m a.g.l. from WRF simulation at 5 km × 5 km grid spacing for the period 2004 to 2013 inclusive. The standard conditions are flat terrain with uniform surface roughness length (10 cm). The colour scale indicates the wind power density in W m$^{-2}$. Note: for the power density calculation only the air density is constant at 1.25 kg/m$^3$. 
Figure 9 – Example of the data contained within a generalized wind climate file data. This data can be used in the WASP software to make predictions of the wind resources at a specific site of interest accounting for the microscale effects due to orography and surface roughness changes. The location is close to Launakalana.
Figure 10 – Top: The location of the generalized wind climate data for the whole of Papua New Guinea shown in Google Earth. Bottom: A detail of generalized wind climate data coverage including how a user of the data can find out about the data filename using Google Earth.
5 Discussion and recommendations

An important issue to investigate further is whether the associated forest surface roughness length in the standard WRF modelling system needs to be changed. The standard roughness for a grid square composed of broadleaf evergreen trees is 0.5 m, which seems too low for such dense tropical forests. The generalization post-processing does take care of local errors in surface roughness, but effects of a surface that is too smooth at the mesoscale might be important. Once measurements are available, a sensitivity study will be conducted varying the forest roughness through comparisons with local measured wind climates.

The measurement data is essential to the validation work required in Phase 3. Suggestions for regions for the measurement masts are given in Section C. The regions are chosen because they represent distinct locations with comparatively high wind speeds. The regions are meant solely for guidance and only depict the regions from a wind climate perspective. Many other factors need to be considered (such as land ownership, ease of access, security etc) before finalizing measurement locations.

Through the measurements a better understanding of the wind energy relevant meteorology of the country will be gained, an improved configuration of the modelling system will be developed and tested, and an uncertainty estimate of the final wind atlas can be determined.

6 Conclusions

This report has described the Phase 1 interim mesoscale wind modelling for Papua New Guinea. The simulation methodology, the configuration of the WRF model and the generalization method have been reported. The results of the wind modelling are presented in the form of simulated and generalized wind maps, and in the form of generalized wind climate data files.
References

A Detailed description of generalization

A.1 Basic generalization equations

The generalization of WRF model winds is an extension of the KAMM/WAsP generalization method described in Badger et al. (2014). In the first step, the time series of wind speed and direction are corrected for orography and roughness change, which are a function of wind direction and height. Given a time series of wind speed, \( u = u(z, t) \), and wind direction, \( \phi = \phi(z, t) \), which are functions of height and time, intermediate values, \( \hat{u} \) and \( \hat{\phi} \), are given by

\[
\hat{u} = \frac{u}{(1 + \delta A_o)(1 + \delta A_r)} \tag{1}
\]

\[
\hat{\phi} = \phi - \delta \phi_o, \tag{2}
\]

where \( \delta A_o \), \( \delta \phi_o \), and \( \delta A_r \) are generalization factors for orography in wind speed and direction and roughness change, respectively. From the time series of corrected wind speed and direction "wind classes" are determined. The binning is based on wind direction sectors, wind speed and surface stability according to the Obukhov length as described in section A.2. From the binning, mean values of wind speed, \( \bar{u} \), and wind direction, \( \bar{\phi} \), and typical Obukhov length \( \bar{L} \), together with the frequency of occurrence, \( F \), of each bin are determined. For simplicity, we will drop the over-bar from the equations that follow, but it is understood that they are applied to the mean values of each bin and not the individual time series values.

From the corrected wind speed value we obtain an intermediary friction velocity, \( \hat{u}_* \)

\[
\hat{u}_* = \frac{\kappa \hat{u}}{\ln(\hat{z}/\hat{z}_0) + \psi(\hat{z}/\bar{L})} \tag{3}
\]

where \( \hat{z}_0 \) is the downstream surface roughness length and \( \psi \) is a stability correction function that adjust the logarithmic wind profile due to non-neutral stability conditions and \( \kappa \) is the von Kármán constant. The stability correction uses the relationship:

\[
\psi(\hat{z}/L) = \begin{cases} 
-31.58[1 - \exp(-0.19\hat{z}/L)] & \text{if } x \geq 0 \\
2 \log[0.5(1 + x)] + \log[0.5(1 + x^2)] - 2 \tan^{-1}(x) + 1.5746 & \text{if } x < 0
\end{cases} \tag{4}
\]

where \( x = (1 - 19\hat{z}/L) \). We use this function with a typical value of the Obukhov length from each wind class bin (see table 2). This procedure avoids using the similarity theory on wind profiles that lie outside the bounds of validity of the theory and that sometimes occur in the WRF simulations.

In the next step, we use the geostrophic drag law, which is used for neutral conditions to determine nominal geostrophic wind speeds, \( \hat{G} \), and wind directions, \( \alpha_G \), are calculated, using the intermediate friction velocity and wind direction:

\[
\hat{G} = \frac{\hat{u}_*}{\kappa} \sqrt{\left(\frac{\ln \frac{\hat{u}_*}{\hat{z}_0} - A}{B} \right)^2 + B^2}, \tag{5}
\]

\[
\sin \hat{\phi}_G = -\sin^{-1}\left(\frac{B \hat{u}_*}{\kappa \hat{G}}\right). \tag{6}
\]
where \( A = 1.8 \) and \( B = 5.4 \) are two empirical parameters and \( f \) is the Coriolis parameter, and \( \hat{\phi}_G \) is the angle between the near-surface winds and the geostrophic wind. Near the equator, where \( f \) can become too large or undefined, it is reset to its value at a latitude of \( 10^\circ \).

To obtain a new generalized friction velocity, \( \hat{u}_G \), for a standard roughness length \( z_{0,\text{std}} \), Equation 5 is reversed by an iterative method,

\[
\hat{G} = \frac{\hat{u}_G}{\kappa} \sqrt{\left( \ln \frac{\hat{u}_G}{z_{0,\text{std}}} - A \right)^2 + B^2},
\]

(7)

Finally, the generalized wind speed, \( u_G \), is obtained by using the logarithmic wind profile law

\[
u_G = \frac{\hat{u}_G}{\kappa} \ln \left( \frac{z}{z_{0,\text{std}}} \right).
\]

(8)

</tbody>
</table>

To apply the generalization procedure to the WRF-model output, winds from the mesoscale model simulations are binned according to wind speed (usually in 2.5 m s\(^{-1}\) bins), wind direction (usually 48 sectors of 7.5\(^\circ\) width) and seven stability class based on the Obukhov length that is also an output from the WRF simulation. The ranges for the stability classes are listed in Table 2 together with the “typical” length used in the generalization.

The procedure is carried out for each model grid point independently. In practice, time series of wind speed and direction at the desired vertical levels and \( 1/L \) are extracted from the model output files. The generalization procedure is then carried out on each time series file.

#### A.3 Weibull distribution fit

The frequency distribution of the horizontal wind speed can often be reasonably well described by the Weibull distribution function (Tuller and Brett, 1984):

\[
F(u) = \frac{k_w}{A_w} \left( \frac{u}{A_w} \right)^{k_w-1} \exp \left[ - \left( \frac{u}{A_w} \right)^k \right],
\]

(9)
where $F(u)$ is the frequency of occurrence of the wind speed $u$. In the Weibull distribution the scale parameter $A_w$ has wind speed units and is proportional to the average wind speed calculated from the entire distribution. The shape parameter $k (\geq 1)$ describes the skewness of the distribution function. For typical wind speed distributions, the $k_w$-parameter has values in the range of 2 to 3.

From the values of $A_w$ and $k_w$, the mean wind speed $\bar{U} \text{ (m s}^{-1})$ and mean power density $\bar{E} \text{ (W m}^{-2})$ in the wind can be calculated from:

\begin{align}
\bar{U} &= A_w \Gamma \left(1 + \frac{1}{k_w}\right) \\
\bar{E} &= \frac{1}{2} \rho A_w^3 \cdot \Gamma \left(1 + \frac{3}{k_w}\right)
\end{align}

where $\rho$ is the mean density of the air and $\Gamma$ is the gamma function. We use the moment fitting method as used in the Wind Atlas Analysis and Application Program (WAsP) for estimating the Weibull parameters. The method is described in detail in Troen and Petersen (1989). Basically this method estimates $A_w$ and $k_w$ to fit the power density in the time series instead of the mean wind speed.

The Weibull fit is done for the ensemble of wind speeds in each wind direction bin (usually 12 direction sectors) for each standard height (usually 5 heights: 10, 25, 50, 100 and 200 m) and standard roughness lengths (usually 5 roughness: 0.0002 (water), 0.03, 0.1, 0.4, 1.5 m). The 25 Weibull fits for each wind direction sector use the method described above.

This sector-wise transformation of Weibull wind statistics—i.e. transforming the Weibull $A_w$ and $k_w$ parameters to a number of reference heights over flat land having given reference roughnesses—uses not only the geostrophic drag law, but also a perturbation of the drag law, with the latter part including a climatological stability treatment. The transformation and stability calculation is consistent with that implemented in WAsP and outlined in Troen and Petersen (1989), with further details given in Kelly and Troen (2014). The transformation is accomplished via perturbation of both the mean wind and expected long-term variance of wind speed, such that both Weibull-$A_w$ and $k_w$ are affected. When purely neutral conditions (zero stability effects) are presumed for the wind statistics to be transformed, there is still a perturbation introduced, associated with the generalized (reference) conditions in the wind atlas. This perturbation uses the default stability parameter values found in WAsP; it is negated upon subsequent application of the generalized wind from a given reference height and roughness to a site with identical height and surface roughness, using WAsP with its default settings. The climatological stability treatment in the generalization depends on the unperturbed Weibull parameters and effective surface roughness (Troen and Petersen, 1989), as well as the mesoscale output heights and wind atlas reference heights (though the latter disappears upon application of wind atlas data via WAsP).

Figure 11 shows the structure of the resulting WAsP “lib” file. It is structured as Weibull $A_w$’s and $k_w$’s for each sector, height and standard roughness length. The first row contains information about the geographical location of the wind climate represented in the lib-file. The second row lists the number of roughness classes (5), heights (3), and sectors (12), respectively. In the third and fourth row, the actual roughness (m) and heights (m) are listed. Below these header lines, a succession of frequencies of wind direction (1 line), values of Weibull-$A_w$ (1 line) and Weibull-$k_w$ (1 line) for each roughness class and height are printed.
**Figure 11** – Contents of WASP generalized wind climate file. This climate is for a location close to Launakalana.

for each sector (12 sectors per line). This type of file can be used and displayed (Figure 9) in WASP.

nio_tasks_per_group = 0,
nio_groups = 1,
The regions indicated are areas in Papua New Guinea with relatively high wind resources compared to the rest of the domain. The regions can be used as guidance for decisions related to locating high verification masts.

Locations over the spine of the Papua New Guinea Highlands have higher modelled winds enhanced by their elevated exposure. Around Dura Island there are higher modelled winds in the coastal areas. From Port Moresby and southward and eastward there are higher modelled winds due to a combination of orographic blocking and stronger winds coming off the sea. The central spine of New Britain and some coastal areas around the island have higher modelled winds. In particular the western part of the island. Similarly Umboi Island and surrounds have high winds due to the mesoscale channeling in the straits between New Britain and Morobe. Along the chain of islands from Bougainville Island, Latangai Island and Manus, some coastal areas and exposed ridges may have favourable conditions.

This meteorological guidance is intended to be combined with other considerations for wind measurement siting. The suggestion is not to have coverage of all parts of a selected verification region, but to have one or two masts per regions, if possible. By doing so the confidence level of the results will be lifted for the whole verification region. However it may be that other siting constraints make this difficult or impossible.
