August 2006

Abstract

For many in Latin America, the increasing participation of China and India in international markets is seen as a looming shadow of two 'mighty giants' on the region's manufacturing sector. Are they really mighty giants when it comes to their impact on manufacturing employment? This paper attempts to answer this question estimating the effects of trade with China and India on Argentina's industrial employment. We use a dynamic econometric model and industry level data to estimate the effects of trade with China and India on the level of employment in Argentina's manufacturing sector. Results suggest that trade with China and India only had a small negative effect on industrial employment, even in a period of swift trade liberalization like the nineties.

Key words: China, Latin America, Trade, Import Competition, Trade and Labor Market Interactions, Employment

“China and India are seen by many as two mighty giants threatening the jobs of the manufacturing industry”

La Nación Newspaper, Buenos Aires
March 2005

“[We] must not repeat the mistakes of the nineties, when an ‘invasion’ of Chinese products destroyed entire sectors of our industry [...]”

Communiqué of CAME
(Medium Enterprises Association of Argentina)
6 April 2004

1. Introduction

For many in Latin America, the increasing participation of China and India in international markets is seen as a looming shadow of two ‘mighty giants’ on the region’s industrial sector, and one of the major causes behind the significant reduction of employment in the manufacturing industry in the last decade. Are these claims justified? Are China and India, the ‘mighty giants’ driving the secular fall in manufacturing jobs in Latin America?

This paper attempts to provide answers to these questions with a focus on Argentina, which experienced a 31 percent decline in industrial employment over the last decade, while the share of imports from China and India increased six fold. To do so, we draw on a dynamic econometric model where labor demand in each industry is a function of wages, the capital stock, prices and productivity. The last two (prices and productivity) are a function of import and export penetration, and will allow us to identify the impact that trade with China and India is having through these two channels on labor demand in Argentina’s manufacturing sector.

In principle, trade should affect the level of employment across and within sectors. Empirical research on the impact of trade on employment, has found little evidence either way, particularly in developing countries.¹ Using plant level data for Morocco, Currie and Harrison (1997) find only a small impact of trade liberalization on the level of employment. Revenga (1997) did not find any statistically significant relation

¹ See Hoekman and Winters (2005) for a comprehensive survey on the recent empirical evidence on the effects of trade on employment.

between the level of employment and tariffs liberalization in the case of Mexico. Márquez and Pages-Serra (1998) examined the relationship between trade liberalization and employment in Latin America and the Caribbean (LAC) and could not find any substantial effect. A comprehensive study by the IADB (2004), using household survey data for 10 LAC countries, did not find a statistically significant association between the two phenomena. De Ferranti, Perry, Lederman and Maloney (2003) confirm this result for several countries in LAC. In a similar study, that also contemplates the effects of exchange rate appreciations, Haltiwanger et. al. (2004), did not find robust results on the relationship between trade liberalization and changes in net employment in the region. In their paper on the impact of trade liberalization on income distribution in Colombia, Attanasio *et al.* (2004) found no evidence of labor reallocation across sectors. Similarly small employment effects in Latin America are reported in Levinsohn (1999) for Chile, Moreira and Nakberg (2000) for Brazil and Gandelman *et al.* (2005) for Uruguay.

For Argentina, in particular, Galiani and Sanguinetti (2003) only found a small correlation between trade liberalization and the rate of employment in the nineties. Pessino and Andres (2005) attribute the negative effects of trade liberalization on employment to the distortions and rigidities of Argentina's labor market rather than to trade liberalization. Sánchez and Buttler (2002) point to other explicative factors beyond trade liberalization, such as labor costs, access to credit finance, financial and real shocks, informality, etc.

Other studies, such as Altamir and Beccaria (1999), Beckerman (2000), and Damill, Frenkel and Mauricio (2002), on the other hand, point to the accelerated process of trade liberalization combined with exchange rate appreciation, as the main culprits of the net employment loss suffered by the Argentinean manufacturing sector in the last decade. In sum, the evidence presented in these studies is not conclusive. In this paper, we are not concerned about which policies may have been the cause behind that decline, but rather on whether imports from the two rapidly growing Asian economies can explain part of this trend.

Results suggest that increased trade with China can only explain a negligible share of the decline in manufacturing labor demand. Moreover, the increase in overall import penetration during the period could only explain a relatively small share of the decline in manufacturing employment. To be more precise, a 1 percent increase in import penetration leads to a 0.07 percent decline in labor demand. Given that import penetration increased by 79 percent over the sample period (1991-2003), the decline in labor demand that can be attributed to the increase in import penetration is around 6 percent. Given that manufacturing employment declined by 31 percent over the sample period, the increase in import penetration can at most explain 20 percent of the observed loss in manufacturing employment. The other 80 percent had other causes. The increased importance of China as a source of imports had an almost negligible marginal impact on the decline in labor demand associated with the increase on overall imports. A 1 percentage point increase in the share of imports from China, leads to an additional 0.02 percent decline in the growth of Argentina's labor demand. Thus, the six-fold increase in the share of imports from China over the period (from 1 to six percent) could only explain an additional 0.1 to 0.2 percent decline in labor demand. Moreover, an increase in the share of imports from Brazil of 1 percentage point would have a marginal impact that is twice as large, which arguably is still very small. Perhaps more worrying, the small negative impact on employment of increased imports from China and Brazil is concentrated in unskilled labor-intensive sectors. Results for India, the European Union and the United States suggest that an increase in the share of imports from these countries do not have an impact on labor demand (beyond the overall impact of import penetration on labor demand). Increases in exports do not seem to have an impact on manufacturing employment regardless of their destination, with the exception of the Indian market.

The remainder of the paper is organized as follows. Section 2 presents some stylized facts of Argentina's trade liberalization and trade with China and India, as well as the evolution of manufacturing employment. Section 3 presents the theoretical model and the empirical strategy. Section 4 presents the results. Section 5 concludes.

2. Stylized facts

There has been a continuous decline in manufacturing employment in Argentina since the early 1980s. Between 1991 and 2003 industrial employment declined by 31 percent.² Losses in industrial employment were only partially compensated by an increase in employment in the services sector. The net effect on overall employment was negative; that resulted in two-digit unemployment rates over most of the period. It is only from 2003 onwards that manufacturing employment has experienced a recovery.

Simultaneously, the aggregate productivity of the industrial sector increased an average of 6.8 percent for 1991-1999. Productivity increased most in capital-intensive sectors such as iron and steel, electric machinery and transport equipment and least in natural resources and labor-intensive sub-sectors.³

In parallel to these changes in the aggregate level of industrial employment, Argentina experienced a deep and accelerated process of trade liberalization.⁴ The trade-openness coefficient (exports plus imports as a percentage of GDP) went from 6 percent in 1993 to 23.4 percent in 2001, falling to 21.7 percent in 2003 as a result of the economic collapse of Argentina in 2002. Imports as percent of GDP increased from 9 percent in 1990 to 11 percent in 2001, and fall to 8 percent in 2003. Exports as percent of the GDP augmented from 7 percent to 12 percent over the period.⁵ For the manufacturing industry, in particular, import penetration increased by almost 79 percent from 1991 to 2003.

² More dramatically, the manufacturing employment level in 2003 was only 47 percent of its level in 1980.

³ For a comprehensive analysis of the changes in the Argentine industrial employment see Altimir and Beccaria (1999), and Beccaria, Altimir and Gonzalez Rosada (2003). Dussel Peters (2004) offers a comparative analysis with Mexico and Brazil.

⁴ See Berlinski (2004) for a detailed account of the Argentinean trade liberalization process in the 1990s.

⁵ These indicators were calculated with data retrieved from ECLAC (2004)

As shown in Table 1, changes in import penetration and share in the industry's total employment varied significantly across manufacturing sub-sectors in the nineties. However, a clear pattern does not seem to emerge by simply looking at the evolution of these two variables. For instance, sectors such as textile, apparel and footwear experience similar increases in import penetration over the period, but the first two sectors saw their share of total manufacturing employment decline, whereas footwear experience and above average increase in its share of manufacturing employment. More generally, while import penetration increased for all manufacturing sub-sectors in 1991-2003 relative to 1980-1991, only half of these sub-sectors experienced a contraction in their share in total industrial employment.⁶ This prima-facie evidence suggests disentangling the impact that imports had on employment may not be straightforward.

The growing importance of China and India as a trading partner is a relatively new phenomenon for Argentina. Figure 2a shows that imports from China, and to a lesser extent India, have started representing a non-negligible share of Argentina's imports only in the mid-1990s. Though the share of China in Argentina's total imports remained relatively low, it increased almost six-fold between 1990 and 2003. Likewise India's share increased almost seven-fold. Figure 2b reports the same information for Argentina's main trade partners: Brazil, the European Union (EU) and the United States.⁷

The already small share of imports sourced in China in total imports declined severely as a result of Argentina's economic collapse in 2001 and only recovered from 2003 on. Imports from India were not an important share of total imports over the entire period. Only from 2002 onwards, imports originated in India have amounted to more than 1 percent of total imports.

⁶ In some sectors (i.e. miscellaneous petroleum products and fabricated metal products) the employment contraction is mostly explained by the radical process of privatization underwent by Argentina's public sector in the nineties.

⁷ These three countries accounted for almost 70 percent of Argentina's imports during the period 1980-2003.

On the other hand, trade with China and India is mostly of an inter-industry nature (that is, trade of goods between different industry classifications) as pointed by very low intra-industry trade indicators.⁸ At the same time, both imports and exports from and to these markets are extremely concentrated in a few products.⁹ This suggests that the potential for across sector reallocation of labor could be important.

Thus, it is important to capture these trends at the industry level. Table 2 shows information on China's import penetration for 28 manufacturing industries between 1980 and 2003. In the nineties, China's import penetration was concentrated in a few sectors, mostly capital-intensive, such as electric and non-electric machinery, scientific and professional instruments and other manufactures. These sub-sectors are the ones facing more competition from imports from all sources not only from China. Some labor-intensive sectors such as leather, and furniture also faced relatively higher import competition from China.

Likewise Table 3 describes import competition from India. Although import competition from India increased slightly in the nineties vis-à-vis previous decades, it remained at very low levels. In fact, with the exception of industrial chemicals, imports from India represented less than 1 percent of Argentina's output.

To summarize, the prima-facie evidence regarding the impact of increases on import penetration on employment in Argentina is mixed. Moreover, the rapid growth in imports from China and India is even less likely to have had a significant impact given that they still represent a small share of Argentina's imports.

However, this quick look at the data does not obviously imply causality, and can be misleading. It would be misleading if, for example, there is correlation between the

⁸ For instance, Castro et.al. (2005) report a Grubel-Lloyd (GL) Coefficient of 0.01 for Argentina-China trade in 2003 (and similar or lower figures for previous years). India displays similar values. The GL coefficient is a statistical indicator of the extent of intra-industry trade (IIT) with the world or a partner within an industry or the whole. The GL coefficient ranges from 1 to 0. A GL coefficient equal to 1 means that all trade in that trade flow is of an intra-industry nature; a GL equal to 0 that trade is purely inter-industry. See Fontaine and Freudenberg (1997) for a complete explanation of the GL coefficient and its variants.

⁹ Castro et.al. (2005), op. cit.

evolution of import penetration and import shares from China and India with other forces that had a significant impact on manufacturing employment in Argentina. It would also be misleading in the presence of reverse causality: import penetration is increasing because employment is declining. To try to identify the role-played by trade and the growth of Argentina's trade with China and India we turn to a more formal empirical model that will help us address these issues.

3. The model and the empirical strategy

In order to estimate the impact of changes on import penetration on labor demand, we follow Greenway et. al. (1998), and assume a Cobb-Douglas production function across industry and time:

$$q_{it} = A_{it} k_{it}^{\alpha} l_{it}^{\beta} \quad (1)$$

where q is real output, k is capital stock, l are units of labor employed, and A is a Hicks-neutral productivity term; α and β are the share of each factor used in total output. We further assume that labor markets are perfectly competitive. Solving the first order condition for labor yields:

$$l_{it} = \beta p_{it} q_{it} / w_{it} \quad (2)$$

where p is the domestic price of the good i and w is the labor wage. Replacing (1) in (2) and rearranging the equation yields the following expression:

$$l_{it} = \beta p_{it} \left[A k_{it}^{\alpha} l_{it}^{\beta} \right] / w_{it} \quad (3)$$

We then solve (3) for labor demand of industry i at time t :

$$l_{it} = \left\{ \left(p_{it} \beta A k_{it}^{\alpha} \right) / w_{it} \right\}^{(1/(1-\beta))} \quad (4)$$

In contrast to Greenaway et.al (1998), we do not condition labor demand on output but on the capital stock. Thus, we allow output to vary following changes in domestic

prices associated with changes in trade liberalization. This may be an important channel through which trade affects the level of employment at the industry level. One would expect the impact of import penetration on labor demand to be larger when conditioning on capital rather than on output, as the former allows for the adjustment of output as import penetration changes. By conditioning labor demand on output, the only channel left for changes in import penetration to affect employment is through its impact on total factor productivity (TFP). This is likely to be positive, as it reduces x-inefficiencies, less efficient firms exit and more efficient firms become larger in the industry. By conditioning on capital, we allow imports to affect employment through changes in both TFP and domestic prices leading to changes in output.

More formally, we assume that $A_{it}p_{it}$ is a function of import and export penetration:

$$Ap_{it} = e^{(\lambda_0 T_i)} M_{it}^{(\lambda_1 + (1/\eta^M))} X_{it}^{(\lambda_2 + (1/\eta^X))}, \quad \lambda_0, \lambda_1, \lambda_2 > 0 \quad (5)$$

where T is a time trend, M is a measure of import penetration, X is a measure of export penetration, η^M is the import demand elasticity, and η^X is the export supply elasticity.

Whilst η^M is negative and therefore an increase in imports will decrease p_{it} (and therefore employment) through this channel, η^X is positive and therefore an increase in exports will increase p_{it} (and consequently employment) through this conduit.

Replacing equation (5) into (4) and taking logs, yields:

$$\ln l_{it} = \alpha_0 + \alpha_1 \ln K_{it} + \alpha_2 \ln w_{it} + \alpha_3 \ln M_{it} + \alpha_4 \ln X_{it} + \alpha_5 T + \varepsilon \quad (6)$$

Equation (6) is the basis for our empirical model using both industry and time dummies. Time dummies capture not only the time trend of the productivity parameter, but also any general liberalization program that would have occurred (an overall 10 percent cut in tariffs) or increase in tariffs for that matter, as well as the impact of changes in the exchange rate or any other macroeconomic shock, such as

the 2001 crisis. Industry dummies capture industry particularities, such as the fact that some of the industries (petroleum products) were subject to significant privatization during the 1990s. So the estimates refer to the within industry impact of trade liberalization on industry employment, controlling for macroeconomic shocks and the general equilibrium effects of a general trade liberalization with year dummies.

Because we are interested in the impact that Argentina's trade with China and India had on manufacturing employment, we also add to equation (6), their share of total imports and exports, as well as the import and export share of Argentina's three main trading partners (Brazil, the European Union, and the United States) to capture the marginal impact associated with trade with different partners. Finally, we also examine whether unskilled labor tends to be relatively more affected by interacting unskilled and skilled labor dummies with the trade shares.

3.1. Empirical Strategy

There are two problems with the estimation of equation (6) that can bias our estimates. First, labor demand is likely to show inertia, and this may lead to first-order serial correlation in the errors. Second, wages and capital stocks are potentially endogenous variables (although theoretically we have treated them as exogenous).

We address the potential serial correlation of the error term by including lagged employment as an explanatory variable, and testing for first and second order correlation of the error term after introducing the lagged dependent variable. This also provides us with long run elasticity estimates. However, as shown in the mainstream literature (see Kiviet, 1995), the inclusion of a lagged dependent variable in a panel setting also leads to biased and inconsistent estimates when using ordinary-least-squares. Thus, we follow Blundell and Bond (1998) and estimate a system GMM using STATA's `xtabond2` command.¹⁰

We address the second problem by using the first, second and third lagged values of wage and capital, as instruments for wages and capital stocks; and the first, second

¹⁰ See Roodman (2005).

and third lagged values of our additional instruments: a proxy for transportation costs, sector value added, and the share of low-skilled labor in each industry.¹¹

4. Results

Table 4 reports the estimates of equation (6) using a System GMM, but also the output-constrained model as in Greenaway et al. (1998). The capital-constrained model results reported in the first column of Table 5 has the expected signs; wages and capital are statistically significant at 1 percent, as well as the lagged dependent variable.¹² Capital seems to have a complementary effect on employment, as indicated by the positive sign of its coefficient.¹³ Import penetration is highly significant at the 5 percent level. According to these results, a 1-percentage point increase in import penetration tends to reduce employment by 0.084 percent in the short run and 0.15 percent in the long run. Export penetration has a positive, but statistically insignificant coefficient.

The second column reports the results of the model where estimates are conditional on output, and again all coefficients have the expected signs. Interestingly, the estimated coefficient on import penetration is 60 percent smaller than in the case of the model conditional on capital. Note, however, that they are not statistically different from each other.

Note that the HO hypothesis of no second order serial correlation of the error term cannot be rejected in both regressions, and the HO hypothesis of no over-identification needs to be rejected. This suggests that there is no evidence that our estimates are biased due to serial correlation of the error term, or lack of identification in our regressions.

Table 5 reports the System GMM estimations only for the capital-constrained specification, but including trade shares by partner, in order to assess the marginal

¹¹ See Data Appendix for a description of the methodology and statistical information used for the construction of each variable.

¹² Our estimates for wages and lagged employment are within the range of estimates obtained for other countries in the region using similar specifications. See Hamermesh (2004). There he provides a summary of the results of the existing econometric studies on trade and changes in the derived static and dynamic labour demand in Latin America.

¹³ See Hammermesh (1993)

impact of imports and exports with different trading partners. The coefficients on lagged employment, wage and capital stock show the expected signs and are highly significant, and stable throughout specifications. The total import penetration coefficient is always negative and significant around the 1 to 5 percent threshold. As shown, an increase of 1 percentage point in total import penetration generates a job loss of around 0.07 percent. Given that import penetration increased by 79 percent over the sample period (1991-2003), the decline in labor demand that can be attributed to the increase in import penetration is around 6 percent in the short run and 10 percent in the long run. Given that manufacturing employment declined by 31 percent over the sample period (1980-2003), the increase in import penetration can at most explain 32 percent of the observed loss in manufacturing employment. The coefficient on Total Exports/Consumption shows the expected sign, but it is not statistically significant.

The last two columns explore the marginal impact on employment of imports and exports with China, India and Argentina's three main trading partners. In the case of China, the coefficient on imports is negative and significant at the 5 percent level in both columns. This implies that, *ceteris paribus*, an increase of 1 percentage point in the share of Chinese imports generates a decrease in labor demand of around 0.02 percent (and around 0.04 percent in the long run). Thus, the six-fold increase in the share of imports from China over the period (from 1 to six percent) could explain an almost negligible 0.1 to 0.2 percent additional decline in labor demand. Interestingly, an increase in the share of imports from Brazil of 1 percentage point would have an impact that is twice as large, which arguably is still very small. Imports from India, or the European Union and the United States do not appear to have any additional impact on employment levels. Exports to different trading partners do not seem to have any additional impact on employment, except for exports to India, but its economic significance is negligible. Again, all four regressions in Table 5 cannot reject the null hypothesis of no second order serial correlation in the error term and reject the null hypothesis of no over-identification.

Table 6 reports the results for the third column in Table 5, but exploring for heterogeneity across industries' labor-skill intensity. Results suggest that the marginal

(and small) additional impact of imports from both China and Brazil is concentrated in low-skill intensive industries. In the case of China, an increase of 1 percentage point in its import share leads to a decline in the employment of unskilled-intensive sectors of around 0.02 percent. The effect is again twice as large for Brazil. In contrast, high-skilled sectors seem not to be affected by imports sourced from either China or Brazil. Again, the over-identification and the second order serial correlation tests do not suggest that there are problems with this regression.

5. Conclusions

Over the last decade, import penetration in Argentina's manufacturing sector increased by 79 percent, while imports from China and India increased six-fold, and manufacturing employment declined by 33 percent. Many believed that the sharp decline in employment was mainly due to the rapidly growing imports from the two Asian economies. A more careful look suggests that the evidence is mixed at best. Total import competition increased significantly across sectors but manufacturing employment (measured as a share of total employment in the industry) decline for some sub-sectors and increased for others. With the exception of apparel and footwear, employment did not decline in sectors where China and India had a significant and growing share of Argentina's imports. Moreover, the two Asian economies still only account for less than 6 percent of Argentina's import bundle.

In order to take a more careful look at whether imports from China and India are responsible for the decline in manufacturing employment in Argentina, we develop a dynamic econometric model, where import penetration and export penetration can affect the level of employment through their impact on domestic prices and productivity, while controlling for industry and time effects.

Results suggest that the rapid increase in import penetration in Argentina's manufacturing employment can only explain a small fraction (20 percent) of the large decline in manufacturing employment observed during the period. Imports from China had a slightly larger impact on manufacturing employment than imports from

the rest of the world, probably due to the fact that China is a relatively labor abundant country. However, the marginal impact of imports from Brazil is twice as large as imports from China, although economically still insignificant. Imports from India or Argentina's other two main trading partners (the European Union and the United States) do not seem to have any additional marginal impact (beyond the impact of import penetration) on manufacturing employment.

Imports from both China and India tend to impose larger declines on the level of employment in unskilled-intensive sectors, although again the marginal effect on unskilled employment of imports from Brazil is twice as large as imports from China. Again, imports from other sources do not have a statistically significant impact when exploring the heterogeneity across skilled and unskilled intensive industries.

Perhaps surprisingly, exports do not seem to contribute to manufacturing employment. The coefficient on export penetration is always positive, but never statistically so. Moreover, even if they were statistically significant, the magnitude of the impact is rather small, given the estimated coefficients. This holds regardless of the export destination, with the exception of India, but again the magnitude is negligible. This suggests that increases in exports are not accompanied by increases in manufacturing employment.

To conclude, the decline in Argentina's manufacturing employment can only marginally be attributed to import competition from China and India, or from any other source for that matter. The "mighty giants" that could explain this decline are to be found somewhere else.

Data Appendix: Sources and variable construction

Our main source is the UNIDO INDSTAT Database of Industrial Statistics at the 3-digit, ISIC Revision 2 nomenclature. It comprises output, wages, employment and value added data for 28 manufacturing sectors, covering the years 1980-2003. The latter was used as an instrument in our estimations. All variables (except for the number of employed people) were converted to 1976 constant dollars using a GDP deflator retrieved from the US BEA (Bureau of Economic Analysis).

In addition, we computed an initial capital stock using the ECLAC-PADI database, adjusted later using (scarce) gross fixed investment data found in the UNIDO database, applying the permanent inventory method. Trade data was gathered from UN COMTRADE and then converted to 1976 constant dollars, except for transport costs, later used as an additional instrument in our econometric estimations. We calculated freight costs per mile using US Imports data from Argentina, gathered from US ITC and BLS sources. Then, we computed total freight costs multiplying freight costs per mile by each trading partner's distance to Argentina using the CEPII distance database. Finally, we applied a simple average in order to avoid collinearity issues with other explanatory variables.

Another variable of interest used as instrument in our estimations is the share of unskilled workers by industrial sector. This was gathered from INDEC (National Institute of Statistics and Census), using all household surveys (EPH) available for Greater Buenos Aires. Any person with unfinished secondary education or less was considered low skilled throughout the whole sample. Since we found some gaps in the data, missing years were filled with the averages of immediate passed and future observations, since it is highly unlikely to encounter sudden structural changes in the skill intensity of each industry from one year to another.

Summary of Data: Available years and Sources

| Variable | Years | Sources |
|--|--|---|
| Output Employment Wages Value Added | 1980-2003 | UNIDO INDSTAT Database |
| Capital Stock | 1980-2003 | ECLAC-PADI / UNIDO INDSTAT |
| Transport Cost | 1991-2003 | US ITC (International Trade Commission), BLS (Bureau of Labor Statistics), CEPII distance database, UN COMTRADE |
| Imports and Exports | 1980-2003 | UN COMTRADE |
| Share of Low Skill Workers | 1980,1982,1985,1987,1988, 1990-2003 | INDEC (National Institute of Statistics and Census) – EPH – Greater Buenos Aires |

Variables

1. **Total Import Penetration:** Total Import penetration for sector i in year t is defined by the ratio between Imports (M) from a specific partner p (in our case the World) and apparent consumption, calculated as

$$Penetration^p_{it} = \frac{M^p_{it}}{Q_{it} - X_{it} + M_{it}}$$

Where Consumption is the expression found in the denominator. Accordingly, Consumption equals Output (Q) plus Total Imports (M) minus Total Exports (X) for each manufacturing sector i and year t .

2. **Total Exports / Consumption:** Total Exports / Consumption ratio for sector i in year t is defined by the ratio between Exports (X) from a specific partner p (in our case the World) and Consumption

$$Export / Consumption^{p}_{it} = \frac{X^{p}_{it}}{Q_{it} - X_{it} + M_{it}}$$

3. **Share of Imports by trading partner:** is the ratio of imports M from partner p and Total Imports for each manufacturing sector i and year t .

$$S^{I,p}_{it} = \frac{M^{p}_{it}}{\sum_p M_{it}^p}$$

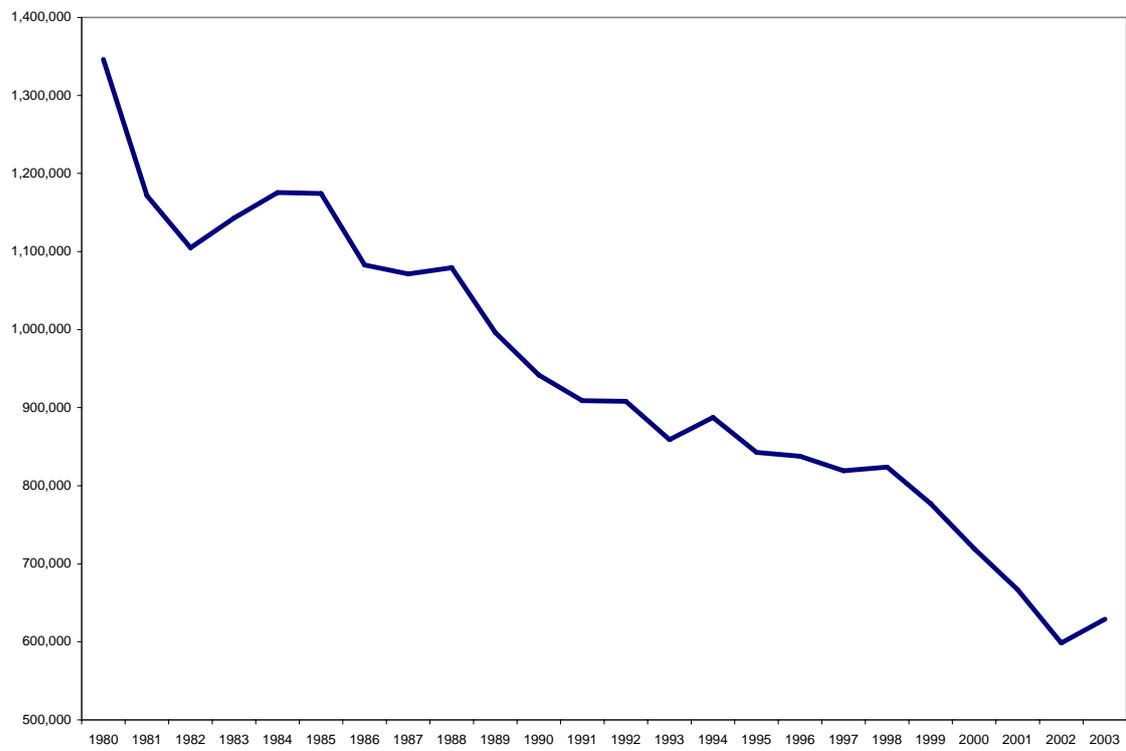

4. **Share of Exports by trading partner:** is the ratio of exports X to partner p and Total Exports for each manufacturing sector i and year t .

$$S^{X,p}_{it} = \frac{X^{p}_{it}}{\sum_p X_{it}^p}$$

5. **Low / High Skill:** Low (High) Skill is a dichotomous variable that takes a value of 1 when a particular sector i in year t has a lower (higher) share of Low (High) Skilled workers compared to the industry average.
