Nearly one-fifth of under-five deaths could be prevented with optimal feeding. Poor nutrition at a young age may also have irremediable consequences for brain development, cognitive skills, and productivity in adult life.

Malnutrition has severe consequences for children. Poor nutrition weakens children’s immune systems, putting them at a greater risk of falling sick from preventable illnesses such as pneumonia and diarrhea. According to Horton et al. (2008), nearly one-fifth of under-five deaths in the world could be prevented with optimal feeding. Research also suggests that poor nutrition at a young age may have irremediable consequences for brain development, cognitive skills, and ultimately productivity in adult life. Unfortunately, a large share of children in the developing world are malnourished. The question considered in this brief is whether early childbirth (defined as a child being born of a mother younger than 18), which in many countries is the result of child marriage, contributes to under-five malnutrition in a significant way in the Republic of the Congo. The brief is part of a series of similar standardized country-specific briefs on the same topic for a number of countries.

Box 1: Brief and Series Primer

How is early childbirth defined? Early childbirth is defined in this brief as a child being born of a mother younger than 18. Early childbirth is related to the practice of child marriage.

Why a series on child marriage? Child marriage has significant negative impacts – not only for girls, but also for a range of development outcomes. Demonstrating these impacts will assist governments and others to make the case for intervening to reduce the practice.

What are the topics discussed in the series? The series looks at the impacts of child marriage on health, population, education, employment, agency, and violence, among other outcomes. The welfare, budget, and non-monetary costs of child marriage are estimated. Legal/institutional aspects and options to reduce the practice are also discussed.

What is the question asked in this brief? The question is: What is the impact at the margin of an early childbirth on the probability of malnutrition (stunting) for children under-five years of age?

How is the question answered? Econometric analysis of Demographic and Health Survey data is used to estimate the impact of an early childbirth on under-five malnutrition.
Statistically, children from young mothers in the Republic of the Congo are eight percentage points more likely to be stunted than if the mother is between 18 and 34 years of age. The focus in this brief is on stunting as a measure of persistent exposure to malnutrition with potentially severe long-term consequences throughout a person’s life (see box 2 on indicators used to measure malnutrition). The analysis is based on data from the 2011-2012 Demographic and Health Survey for the Republic of the Congo. Estimates suggest that 30.32 percent of children born of mothers younger than 18 are stunted. The proportion is still high, but eight points lower at 22.58 percent for children born of mothers 18 to 34 years of age. The difference in stunting rate between these two age groups is statistically significant. For children of mothers older than 35, the incidence of stunting was also lower at 21.89 percent.

**Box 2: Measures of Malnutrition**

Three main measures of malnutrition are used in applied work. A child is considered underweight if s/he has a weight more than two standard deviations below the reference median weight for the child’s age. A child is considered wasted if s/he has a weight to height ratio more than two standard deviations below the median weight for height for the reference population. A child is considered stunted if s/he has a height more than two standard deviations below the median reference height for that age. If a child on any of these measures is below three standard deviations of the norm, s/he is considered as severely underweight, wasted, or stunted. Among the three measures, stunting and wasting tend to be used the most. Stunting often results from persistent insufficient nutrient intake and infections. It may lead to delayed motor development and poor cognitive skills that can affect school performance as well as productivity and earnings later in life. Wasting tends to result more from acute food shortage or disease and may lead to death. For the purpose of this brief, given a separate brief of under-five mortality, stunting is the best measure to focus on.

Controlling for other factors, early childbirth does not increase the likelihood of stunting substantially.

The difference in the likelihood of stunting between children of young and older mothers does not necessarily imply a causal effect of the age at delivery, but it does suggest that early childbirth may contribute to stunting. To check whether controlling for other factors early childbirth is associated at the margin with higher under-five malnutrition, regression analysis is used (see the annex for details on the methodology).

Table 2 provides key results with baseline and extended models. The interpretation of the coefficients is in terms of marginal impacts in percentage terms. For example, a statistically significant coefficient of 0.05 for a mother younger than 18 would indicate that children of very young mothers have a likelihood of stunting five percentage points higher than otherwise similar children of older mothers.

With the baseline specification, table 2 indicates that deliveries at a young age do not significantly increase the likelihood of stunting for the children in comparison to a delivery at 18 to 34 years of age (in the Republic of the Congo). The difference in risk of stunting between mothers ages 18-34 and mothers above 35 is however statistically significant.

In the Republic of the Congo, delivery at a young age does not increase the likelihood of stunting for the child in comparison to a delivery at 18 to 34 years of age.

Marginal effects do not change much when additional controls are added (extended model). There is thus some evidence that in the case of the Republic of the Congo, after controlling for a wide range of other variables, early childbirth may not contribute to stunting, but prudence remains needed when interpreting these results given the risk of omitted variable bias (see box 3).

**Box 3: Risk of Omitted Variable Bias**

In many countries, although not in the Republic of the Congo, early childbirth appears to be positively correlated with the risk of stunting after controlling for other factors that may also contribute to stunting. This could indicate a causal effect. However, other variables correlated with both early childbirth and stunting not included in the analysis could be at the source of the correlation between early childbirth and stunting. Because of the risk of omitted variable bias, the results cannot be considered as fully conclusive regarding a causal impact of early childbirth on the risk of stunting.

A number of results from the regression analysis not shown in table 2 are worth mentioning. The impact of wealth on the likelihood of stunting is statistically significant in the two highest wealth quintiles. For example, children in the highest quintile (the richest 20% of households) have a likelihood of stunting sixteen percentage points lower than children in the poorest 20% of households. This is not surprising, and could be due to the fact that households in the bottom quintiles are poor or near poor in a country like
the Republic of the Congo. Given that the incidence of stunting is so high, whether a household is extremely poor, or simply poor, does not make much of a difference on the likelihood that children will be stunted.

As shown in table 3, the marginal impact of a mother having a secondary education or better on the likelihood that her child will be stunted is not statistically significant, which is somewhat surprising.

Note though more generally that the inclusion of education as a control points to the possibility of indirect effects of early childbirth on stunting. Because early childbirth may have an impact on other variables used as controls in the regression, its overall effect on stunting, including indirect effects through these other variables, may be larger than the (non-significant) direct effect documented in table 2. For example, for some girls having a baby at a young age, early childbirth could have reduced education attainment, which could lead to a higher risk of stunting (although not in the Republic of the Congo according to the regression results). In addition, early deliveries, by increasing the number of household members may also contribute to lower standards of living. In the Republic of the Congo, as mentioned earlier, the regression results suggest that the level of welfare as measured through wealth quintiles have an effect on stunting.

Simulations suggest that very few children under-five are stunted directly due to early childbirth.

Because only a small share of deliveries are by mothers younger than 18, very few stunted children can be said to be stunted directly due to early childbirth.

Conclusion

Early childbirth may contribute to the risk of malnutrition for children, directly and indirectly. This brief has provided estimates of the direct impact of early childbirth on stunting in the Republic of the Congo using the latest DHS survey. More than two in ten children under the age of five are stunted. Controlling for socio-economic and other characteristics, being born of a mother younger than 18 does not have a statistically significant effect on the likelihood of stunting as compared to otherwise similar children born of older mothers. This, together with small indirect effects of early childbirth through education in the Republic of the Congo, suggests that few children are stunted directly or indirectly because of an early childbirth, even though some may be.

References

There is no doubt that children born to very young mothers are more likely to be malnourished than other children, but this might not specifically be due to the fact that the mothers are young. Girls who have children before the age of 18 tend to be poorer. This implies that their children are at higher risk of inadequate nutritional intake. Early pregnancies are more common in areas where access to healthcare is limited to prevent or treat malnutrition. Young girls also often suffer from a lack of agency and decision-making power in the household, which may reduce their ability to seek care for their children when needed. Girls who give birth early are likely to have dropped out of school due to pregnancy or marriage, which may also affects the nutritional status of their children due to lack of education or knowledge on how to best take care of young children.

These risk factors correlated with early childbirth do not necessarily imply that early pregnancies by themselves contribute in a direct way to child malnutrition. Controlling for other factors, it could be that early childbirth does not lead to a higher risk of malnutrition for children. But it could also be that there is a direct causal link between early childbirth and child malnutrition, for example if some young mothers giving birth are not yet be ready physiologically to give birth, which could in turn affect the health of their children. This brief estimates the direct impact of early childbirth on under-five malnutrition.

In addition, the brief provides an assessment of the extent to which under-five malnutrition would be reduced if early pregnancies/deliveries were eliminated. In order to measure the potential impact of early childbirth at the margin on stunting for children under the age of five, regression analysis is used. In the more detailed paper on which this brief is based, both tobit regressions (to measure the degree of stunting among children who are stunted) and probit regressions (to measure the likelihood of stunting) are provided.

In this brief, due to space constraints and because of the interest in the share of stunting that could be attributed to early childbirth, the focus is on reporting results from probit regressions. In those regressions, the dependent variable is whether a child is stunted or not.

Different specifications are estimated to assess the robustness of the results to the choice of models. Overall, the results are fairly robust to different specifications. For the baseline model, the independent variables are the following: (1) the age of the mother at the time of delivery by categories; (2) the child's age and gender; (3) whether the child had siblings born at the same time (multiple birth); (4) the birth order of the child and the child's birth weight by categories; (5) the length of time between the child's birth and a previous birth for the mother; (6) whether the child has received recommended immunizations; (7) whether the delivery took place in a health facility and was attended by skilled personnel; (8) the mother's height and education level, as well as whether she works and the type of work involved; (9) the father's occupation and his level of education; (10) the location of the child by region and by urban-rural category; (11) whether the household has access to an improved water source and improved sanitation; (12) whether the household has more than two children under-five; and finally (13) the wealth quintile of the household.

In the extended model, additional controls are added: (14) whether the household practices polygyny; (15) whether the distance to health facility is a major problem for the household; (16) the age gap between the spouses; (17) indicators of decision-making power for the mother; (19) tolerance towards wife beating; and (20) whether the mother is able to get permission to access healthcare.

This brief was produced by a World Bank team as part of the Economic Impacts of Child Marriage study. The synthesis report under the study was produced jointly with the International Center for Research on Women. The study benefitted from support from the Bill & Melinda Gates Foundation, the Children’s Investment Fund Foundation, and the Global Partnership for Education. Comments from colleagues and peer reviewers are gratefully acknowledged. The opinions expressed in this brief are those of the authors only and need not reflect the views of the World Bank, its Executive Directors, of the countries they represent.

**Annex: Methodological Note**

There is an existing literature on the relationships between early childbirth, child marriage, and the risks of under-five malnutrition (e.g., Fall et al., 2015, and Finlay et al. 2011). This literature suggests that children born of young mothers are at higher risk of malnutrition. How much higher in the case of Niger is the question to be answered. To answer this question, this brief focuses on stunting as the measure that tends to best capture persistent exposure to malnutrition with likely long term negative consequences for children.

In addition, the brief provides an assessment of the extent to which under-five malnutrition would be reduced if early pregnancies/deliveries were eliminated. In order to measure the potential impact of early childbirth at the margin on stunting for children under the age of five, regression analysis is used. In the more detailed paper on which this brief is based, both tobit regressions (to measure the degree of stunting among children who are stunted) and probit regressions (to measure the likelihood of stunting) are provided.

In this brief, due to space constraints and because of the interest in the share of stunting that could be attributed to early childbirth, the focus is on reporting results from probit regressions. In those regressions, the dependent variable is whether a child is stunted or not.

Different specifications are estimated to assess the robustness of the results to the choice of models. Overall, the results are fairly robust to different specifications. For the baseline model, the independent variables are the following: (1) the age of the mother at the time of delivery by categories; (2) the child’s age and gender; (3) whether the child had siblings born at the same time (multiple birth); (4) the birth order of the child and the child’s birth weight by categories; (5) the length of time between the child’s birth and a previous birth for the mother; (6) whether the child has received recommended immunizations; (7) whether the delivery took place in a health facility and was attended by skilled personnel; (8) the mother’s height and education level, as well as whether she works and the type of work involved; (9) the father’s occupation and his level of education; (10) the location of the child by region and by urban-rural category; (11) whether the household has access to an improved water source and improved sanitation; (12) whether the household has more than two children under-five; and finally (13) the wealth quintile of the household.

In the extended model, additional controls are added: (14) whether the household practices polygyny; (15) whether the distance to health facility is a major problem for the household; (16) the age gap between the spouses; (17) indicators of decision-making power for the mother; (19) tolerance towards wife beating; and (20) whether the mother is able to get permission to access healthcare.
